

# Handling errors - PHP

---

It is always possible for your request to return an error. If an error occurs, e.g. if your API username/password is incorrect, our wrapper will throw a PHP exception. If you're not familiar with handling exceptions in PHP, it basically means you need to put the wrapper function calls in a try-catch block.

## Example

```
try {
    $sent = $tmClient->sendSMS('My message', '447000000000', 'Sender');
} catch (Exception $ex) {
    $errors = $tmClient->getLastErrors();
}
```

You must decide how to handle errors according to the logic of your particular application. For example, if you're building a web interface to send text messages, and a send fails, you may wish to show a visual alert to the user.

Note that more than one error can be reported at once. Therefore although a single PHP exception (the first of the errors) is thrown, the complete set of errors encountered is available in an array of key-value pairs. The key of each pair is the error code and the value is a detailed description of the error.

## Example

```
foreach($errors as $errorcode => $errormsg)
    echo "Error encountered with code $errorcode: $errormsg\n";
```
